Variability, correlation, path coefficient and genetic diversity analysis in Indian mustard

ABSTRACT

Phenotypic and genotypic coefficient of variation (PCV & GCV), heritability, genetic advance (GA), correlation, path and diversity analysis for fourteen characters in twenty-five genotypes of Indian mustard (*Brassica juncea* L.) were evaluated for seed yield and thirteen other yield contributing traits. Genetic variability indicated that, the PCV was greater than GCV for all the traits studied was majorly due to the influence of environment. High heritability along with high genetic advance as per cent of mean were recorded for plant height, number of primary branches per plant, number of secondary branches per plant, length of main raceme, number of siliquae on main raceme, number of siliquae per plant, 1000 seed weight, biological yield per plant, seed yield per plant and harvest index, Indicating the breeding improvement through direct selection. In correlation analysis, seed yield per plant had significant and positive correlation with number of primary branches per plant, number of secondary branches, number of siliquae on main raceme, number of siliquae per plant, length of siliqua, number of seeds per siliqua, 1000 seed weight, biological yield per plant and harvest index at both genotypic and phenotypic levels. Path coefficient analysis indicated that, the highest positive direct effects was noted for days to 50% flowering, plant height, number of siliquae per plant, number of seeds per siliqua, length of main raceme, number of primary branches per plant, 1000 seed weight, biological yield per plant, harvest index. Therefore, these traits should be given more priority for selection in breeding programme. Genetic divergence assessed using D^2 statistics for characters enabled grouping of all the genotypes in Six clusters. Diversity among the clusters varied from 9.67 to 24.03 inter-cluster distances, cluster II and V showed maximum inter cluster distance followed by that between cluster V and VI. The genotypes falling in these clusters could be utilized for hybridization programme in Indian Mustard.

Keywords: Indian mustard, variability, genetic advance, heritability, correlation, path analysis and diversity.

INTRODUCTION

Oilseed Brassicas, often known as rapeseed-mustard, are a significant category of oilseed crops worldwide, consisting of eight cultivated crops from the Brassiceae tribe of the Brassicaceae family (Cruciferae). The term "mustard" derives from the European practice of preparing a heated paste by combining the sweet 'must' of old wine with crushed seeds of black mustard (*Brassica nigra*) [1]. In India, Indian mustard (*Brassica juncea* (L.) 2n=36) is a major oilseed crop. It is grown for oil, condiments, and therapeutic purposes. However, the crop is mostly grown for the manufacture of edible vegetable oil. Despite belonging to the same family and genus, rapeseed and mustard exhibit unique botanical

characteristics. Rapeseed is an annual herb that grows to a height of 45 to 150 cm. In most situations, a waxy covering covers the stems. Plant leaves are easily distinguished from mustard (rai) plants. Rapeseed leaves are sessile, glabrous, and hairy. The stalk is partially or completely grasped by the lowest segment of the blade (lamina). The fruits are thicker than mustard (rai) and feature a beak that is one-third to half the fruit's length. The seeds are golden or brown in colour, with a smooth seed coat. Mustard plants are tall (90-200 cm), erect, and highly branched. Instead of being dilated at the base and clasping like rapeseed, the leaves are stalked, broad, and pinnatifid. The fruits are narrow, ranging in length from 2 to 6.5 cm, with strong ascending or erect stems and short, thick beaks. The seed has a rough seed coat and is brown to dark brown in colour. Mustard is the world's third most significant oilseed crop, behind soybeans and palm oil. Among the several oilseed crops produced globally, the estimated area, production, and yield of mustard were 34.88 mha, 69.22 mt, and 1.98 Mt/ha, respectively [2]. Rapeseed production, area, and yield in India are 8.30 million hectares, 1.3 million tonnes, and 1.1 million tonnes per acre, respectively. Where rapeseed yield is lower than that of other crops.

Genetic variety and diversity are crucial requirements for crop development because they allow for more selective breeding. Because seed yield is a polygenic characteristic that frequently leads to changes in other characters, the link between seed yield and other traits is useful for selecting the proper selection in breeding programmes. During the selection process, correlation analysis measures the degree, direction, and strength of the association between two or more variables. Path coefficient analysis quantifies the direct and indirect impacts of numerous independent variables on a dependent variable [3]. As a result, the current study is being carried out to estimate the heritability and diversity of genotypes for yield and yield contributing variables, as well as to assess the amount of direct and indirect reasons of linkage among various characters through path analysis in mustard.

MATERIALS AND METHODS

The present investigation entitled "Genetic Diversity and Characters Association in Mustard" was carried out under, Department of Plant Breeding & Genetics at Agriculture Farm, School of Agriculture, Lovely Professional University, Jalandhar (Punjab) during the *rabi* 2021-22. The experimental design comprised 25 different genotypes of Mustard (Table 1) were grown in a RBD with three replications during *rabi* 2021-22. Each plot consists of four rows of 5.0 m length. Five competitive plants were selected from each replication for 14 quantitative traits viz: days to 50% flowering, days to maturity,

plant height, number of primary branches per plant, number of secondary branches per plant, number of siliqua per plant, number of seed per siliqua, siliqua length of siliqua, number of siliqua on main raceme, 1000- seed weight, biological yield per plant, harvest index, seed yield per plant. The mean values of each genotype were computed for statistical analysis. The standard method of analysis of variance was given [4], phenotypic and genotypic coefficient of variation, heritability (Broad Sense) and genetic advance as percent of mean were estimated by the formula as suggested by [5] and [6]. The formula of genotypic correlation coefficients was estimated by [7]. Path analysis along with genotypic correlation coefficient is applied to know the direct and indirect effects of the components on yield as suggested by [8] and illustrated by [3]. The replicated data were subjected to genetic divergence analysis using Mahalanobis's D² - statistic [9].

RESULTS AND DISCUSSION

The analysis of variance indicated that the mean sum of squares due to genotypes were highly significant at 1% and 5% levels for all the traits except for four traits number of primary branches, number of secondary branches, length of siliqua and 1000 seeds weight (g) (Table 2). Similar results were also obtained by [10],[11],[12] and [13] in which analysis of variance showed significant differences for all the characters under their study.

In the present study, the phenotypic coefficient of variation (PCV) was greater than genotypic coefficient of variation (GCV) for all the traits. The high magnitude of both coefficients was recorded for traits; number of siliqua per plant recorded the highest PCV and GCV followed by seed yield per plant, number of siliqua on main raceme, harvest index, biological yield per plant and plant height (Table 3). The estimates of phenotypic and genotypic coefficient of variability for of the characters under study are in accordance with earlier reports, [14],[15],[16],[17],[18],[19],[11] and [20].

High heritability with high genetic advance was recorded for days plant height, number of primary branches per plant, number of secondary branches per plant, length of main raceme, number of siliquae on main raceme, number of siliquae per plant, 1000 seed weight, biological yield per plant, seed yield per plant and harvest index (Table 3). This might be attributed to additive gene action responsible for their expression and hence, phenotypic selection for their amenability, can be brought about. Similar result found, [19] for 1000 seed weight, [21] for number of Siliqua per plant, [22] for 50% flowering, [23],[24] for 50% flowering, plant height, seeds per Siliqua, 1000 seed weight, [25] for seed yield per plant, number of secondary branches, 1000 seed weight, number of seeds per Siliqua, primary branches per plant and Siliqua length, [26],[27],[28] and [29].

The significant phenotypic correlation of seed yield per plant was found positive for the characters namely, number of primary branches per plant, number of secondary branches, number of siliquae on main raceme, number of siliquae per plant, length of siliqua, number of seeds per siliqua, 1000 seed weight, biological yield per plant and harvest index (Table 4). This suggests that these characters should be considered while selecting for improvement in seed yield per plant provided the character should show high variability, which is the basis for selection. However, days to maturity and plant height

showed negative correlation with seed yield per plant. In the present findings, the magnitudes of genotypic correlation coefficient were greater than corresponding phenotypic correlation coefficient (in general also) similar findings by [11],[30],[20],[13] and [19].

The path coefficient analysis of different characters revealed that positive direct effect on seed yield per plant per plant was observed by days to 50% flowering, plant height, number of siliquae per plant, number of seeds per siliqua, length of main raceme, number of primary branches per plant, 1000 seed weight, biological yield per plant, harvest index (Table 5). We can conclude based on present finding that those all character which had positive direct effect on seed yield per plant that universal traits for overall improvement. Negative direct effect on seed yield per plant was exerted by days to 2 maturity, number of secondary branches per plant, number of siliqua on main raceme and length of siliqua. In the present findings, the similar results are also reported by Direct and positive effect by [30],[31],[13],[19],[20],[32] and [31] viz seed yield per plant.

Genetic divergence analysis based on Mahalanobis D2 statistics, twenty-five genotypes were grouped into six clusters in mustard (Table 6). The maximum differences among the genotypes within the same cluster (intra-cluster) were shown by cluster I followed by cluster II. Clusters III, IV & V showed zero intra-cluster distances (Table 7). The genotypes showing maximum diversity from clusters I & II could be utilized directly for future hybridization programs. In conformity to the present investigation, similar findings were found by [33],[34] and [35].

It was observed that biological yield per plant was the highest contributor towards divergence followed by all except Length of main raceme (Table8) don't contribute significantly to the total divergence. Similarly, Devi *et al.*, (2017) was observed, biological yield, Harvest index 1000 seed weight and seed yield per plant were the major contributors for genetic diversity among the genotypes. The cluster mean values for 14 characters of 25 genotypes have been represented in (Table 8).

Table 1: Details of the Genotypes is given below.

Sr. No.	Entries	Pedigree / Source (DRMR)

DF = Days to 50% flowering, DM = Days to maturity, PH = Plant height, NPBP = Number of primary branches, NSB = Number of secondary branches, LMR = Length of main raceme, NSMR = Number of siliqua on main raceme, NSP = Number of siliqua/plants, LS = Length of siliqua, NSS = Number of seeds/siliqua, TSW = 1000 seed weight, BY = Biological yield/plant, SY = Seed yield/plant and HI = Harvest index.

CONCLUSION

The conclusion that can be reached from variability, correlations, path coefficient analysis and genetic divergence is that plant height, number of primary branches, number of secondary branches, number of siliqua on main raceme, 1000 seeds weight, biological yield per plant, seed yield per plant and harvesting index found the most important component characters. Hence, these traits should be considered as selection criteria for yield improvement in mustard.
