Sources of transmission of pathogenic intestinal parasites in humans and vegetables in Omdurman, Sudan - 2015.

#### **ABSTRACT**

This study was designed to investigate the possibility of infection via food with pathogenic organisms. It was carried out in the city Omdurman in Khartoum States during the period from December 2015 to November 2019. The objectives of the study were to identify the causative intestinal parasites in the examined individuals. A total of 600 stool specimens and 256 vegetables samples were examined. Faefecal samples were observed macroscopically for the consistency and presence of mucus, blood, worm larvae and cestodes segments. The samples were then examined by wet smear and formal - ether concentration technique. A bout 200 -300 grams of each vegetable and fruit were washed in 50 ml of sterile normal saline and filtrate was centrifuged and then the sediment was examined microscopically. Result showed that tThe overall prevalence of intestinal parasites microscopically was found to be 29.8% (179/600)(29.8%). Entamoeba histolytica cyst was reported observed in 62.2% in mothers 28 (62.2%) as two fold as in children 13 (28.9%), while in food handlers cysts wasere recorded in 4(8.9%)of food handlers. Gardia Lamblia was more dominated in mothers 48(58.5%) as twice as seen in children 24 (29.3%), whereas 12.2% prevalence

Formatted: Font: Italic

Formatted: Font: Italic

in food a handler was noted in food a handler 10(12.2%). Taenia spp was found only in mothers 5 (71.4%) and children 2 (28.6%). Moreover, Ascaris lumbricoides was also seen in mothers 11(61.1%) and children 7 (38.9%). Among the examined vegetables and fruits samples, G. lamblia was found to be the most dominated parasite 26 (66.7%), followed by E. histolytica 8 (20.5%) and A. lumbrucoides 5 (12.8%) respectively. In conclusion, the overall of the prevalence intestinal parasites and bacteria was more pronounced among mothers and their children's. Gardia Lamblia and E histolytica were the most predominanted parasites seen microscopically among participants. Mothers should be examined periodically for their health status regarding intestinal parasites and bacteria and to increase the awareness prompt detection.

**Key words:** 

Intestinal parasites, Food handlers, Mothers, vegetables, fruits, stool examinationsample

## Introduction

The chain that starts from harvesting crops, transportation, marketing to consumption by individuals is not without hazards. Food contamination due to in-appropriate and inadequate sanitation that may occur in parts of such chain result in public health effects. Parasites and bacteria are the major sources of contamination of food and consequently causative agents of diseases. The intestinal helminths seldomly occurring in; bBacteria present in food will grow under favorable condition and will

common in Sudan (1). Intestinal parasites and bacteria are among the main public health problems around the world especially in tropical and subtropical countries (2). Of the nearly 1500 agents known to be infectious to humans, 66 are protozoa and 287 are helminths. Many vegetables are good sources of vitamin C, thiamine (Vitamin B1), Riboflavin and mineral elements (3). The consumption of raw vegetables plays major sources of transmission of parasitic food borne diseases (2). In recent years, there has been an increase in number of reported cases of food borne illness linked to consuming raw fresh vegetables. Several surveys in different parts of the world showed that the vegetables can be agents for transmissions of intestinal parasites such Cryptosporidium spp., Giardia lamblia, Entamoeba histolytica, Ascaris lumbricoides, hookworms, Enterobius vermicularis, Trichuris trichiura, Toxocara spp., Hymenolepis spp., Taeniaspp., Fasciola spp (3). Vegetables can become may be contaminated with enteric parasitic pathogens (2) throughout the process of planting to consumption. The extent of contamination depends on several factors that include use of untreated wastewater and water supplies contaminated with sewage for irrigation, post-harvest handling, and un-hygienic conditions of preparation in food service or home settings. It was found that fresh vegetables can be factors of transmission of protoaza cysts, helminthes ova and larvae (4).

produce toxins in food. Reports indicate that parasitic and bacterial infections are quite

Khartoum, the capital of Sudan is inhibited by more than 7 million people. They rely on the rural areas on the outskirts of the city for securing, vegetables, meat and milk.

Infective agent gain access via various routes, particularly ingestion of contaminated food and water. In Sudan several reports are available (Ref)on the prevalence of parasitic and bacterial infections in humans but the various sources and the modes of transmission of such agents are not fully explored. The possibility of transmission of parasite to young children by infected mothers is an example, similarly, the role of food handlers in dissemination of agents is not fully investigated.—Information on such areas were can aid in control of pathogenic agents.

#### **Methods:**

## **Study setting:**

This study was a descriptive community-based study. It was conducted in the city of Omdurman including Umbada, Karari, Sabreen and Althora. The study population was comprised of 200 mothers, 200 their children (5 years or less) and 200 food handlers distributed as follows 86 grocery workers, 23 tea sellers, 15 cafeterias, Restaurant's workers, 16 food industry workers, 13 Bakers, 12 Refreshment sellers, 12 Butchers, 12 milkmen and 11 Vegetables and Fruits sellers. Beside vegetables 32 samples for each kind from vegetables and fruits (Lettuce, Cabbage, Molokhia, Green onion, Tomatoes, and Cucumber) and (Mangoes and Oranges). Before collection of samples the purpose of study was explained to the participants to obtain their consent.

## Faecal specimens<sup>2</sup> collection and examination:

**<u>Fa</u>**ecal samples were collected from mothers, children and food handlers in a clean plastic container. Before microscopic examination, faecal samples were observed for consistency, mucus, blood and also for the presence of worm larvae and cestodes segments.

#### Wet mount examination

<u>W</u>wet smear was made by putting a small amount of stool on clean glass slide, mixed with a drop of normal saline-,covered with cover slip and examined microscopically using 10X and 40X objectives.

## Formal ether concentration technique

A small portion of about 2 grams was added to 9 ml of formalin and strained through sienve in a tube and 3ml of diethyl-ether was then added and suspension was mixed and centrifuged at 2000 rpm for one minute. A drop of the sediment was transferred to a slide, covered with slip and examined at 10x and 40x lens (Ref..).

# **Examination of vegetables and fruits**

A-bout 200 -300 grams of each vegetable and fruit were washed in\_50 ml of normal saline and strained through a sieve to remove un desirable materials—. The filtrate was then centrifuged at 5000 rpm for 5 minutes. The supernatant was then decanted and a drop of the sediment was placed onto a slide, covered with a slip and examined microscopically at 10x and 40x objective lens.

## Data collection and analysis

All the questionnaires and stool samples were labeled with the same number to ensure consistency and completeness. Data was entered and cleaned using Statistical Package for Social Sciences (SPSS) version 20. Descriptive statistics was done to assess the prevalence and distribution of intestinal parasites. Logistic regression analysis was performed to determine the independent effect of the independent variables with dependent variable by calculating the strength of the association between intestinal parasites infection and determinant factors using odds ratio (OR) and 95% confidence interval (CI). Crude OR and adjusted OR were estimated by bivariate and multivariate logistic regression analysis with respective 95% CIs respectively. P value less than 0.05 was considered as statistically significant.

#### **Ethical Considerations**

Prior to the commencement of the study approval was obtained from Sudan Academy of Sciences. Permission was also obtained from administrative units of the selected settings. Moreover, mothers or/and the head of the household was informed by the study objectives. Then, a written consent was obtained from participants. Confidentiality during the interview and stool collection was maintained

#### **Results**

The rate of infection microscopically among participants'

Figure 1. showed that the microscopic detection of stool samples reveled those mothers underscored the highest rate of infection among participants 92/600200(15,346%), followed by their children 73/200(12.236.5%) and food handlers 14/600-200(2,37%) respectively.

## **Macroscopic Examination of Stool Samples**

Table 1. below showed that mucus was found similarly in children 27 (40.9%) compared to their mothers 26 (39.4), and constituted as twice likely as in food handlers 13 (19.7%). Blood was detected in mothers 14 (60.9%) as two folds compared to their children 7 (30.3%), while in food handlers it was seen only in 2 (8.7%) cases. Blood and mucus were most prevailed in children 10 (76.9%), while in mothers 2 (15.4%) as twice as food handlers 1 (7.7%). There was sStatistical association was noted between macroscopic examination and different participants' p value (0.03).

Table 4. showed that the rate of infection concerning age groups of children and it was increased gradually with augmenting of the age. eEspecially among those of more than 2 years, 29 cases were detected and 25 cases were recorded in children between 1-2 years old—25 cases. However, the predominated parasites were found to be Hymenolepis nana, Gardia Lamblia and Entamoeba histolytica respectively. There was no significant association seen-between increasing age of child age and type of the parasite (p-value <0.83).

#### **Discussion**

In this study it was found that the percentage of about 15.3% of motherswomen, and 12.2% of children having intestinal parasites in their stool. It also showed 2.3% of Food handles and 15.2% of the vegetables were contaminated with intestinal parasites. This indicate that infected mothers can become a source of infection to their children. Similarly, contaminated vegetables and fruits constitute an important source of infection particularly those fruits which are eaten fresh. Based on these findings, it seems reasonable to conclude that infected mothers are as well as vegetables and fruits can convey internal parasites to their children. In a study conducted in Khartoum by Salim in 1999 showed that the rate of intestinal parasitesi\(\frac{1}{4}\)n the school children in Khartoum was 37.5\(\frac{6}{4}\) and such rate was higher that obtained in the present study (5). As the author used same techniques then such differences may be attributed to the fact that Salim conducted his study among school children who are older and definitely more than 5 years and the numbers of children examined. This can render them more resistant to infection. Similarly, the occurrence of parasites in food handlers was found by Babiker et al., in (2009) to be such higher that the present result (6). The only explanation for much such differences is that the higher number of examined very many individuals examined (n = 1500) compared to those screened here. Elsewhere similar trials generated different results. For example, the rate in village people in Korea was 44% (7). In preschool children in India was 64%, 20% in U.S.A and 9.3% in Saudi Arabia (8-10). This differences in prevalence rates whether higher or lower than we obtained might be attributed to environmental factors. It is clear that mothers have a high prevalence of

intestinal parasites compared to them their under five children and food handlers (8). This fact might be attributed to the negligence of mothers by their health status and/or the absence of regular checkup. Moreover, many mothers have behavior and tendency of treating themselves by using herbs rather to visit doctors. This behavior might be resulted in increasing the infection of intestinal parasites compared to food handlers, because of food handlers should be performed mandatory regular check up every six months to have their good health certificate for continuation their work.

This study found that there was no statistical association between macro and microscopic examinations of stool. This result might be attributed to other confounder factors, where mucus could as result of cancer, whereas blood also might be attributed to cancer and ulcers. The results obtained showed that G.lamblia and E.histolytica were the predominant species in stood stool sampls of mother, children, and food remainder having scored the highest in the 3 categories. Other species such as A. lumbricoides and T. saginata were detected in mothers, children and food handlers and H.\_nana in children only. In vegetables and fruits E.\_histolytica and G.\_lamblia were also presented in almost all the varieties and A. lumbricoidesscaris in 3 vegetables only. In our study there was significant association seen between the infection of mothers and their children regarding intestinal paraites. This fact might be suggested that the transmission of the parasites from mothers to their children occurred miecanically. G. lamblia and E. histolytica were the prevailed species of intestinal parasites in this study in mothers, children, food handlers, vegetables and fruits. This results in compatible with other studies which found that G.\_lamblia and E. histolytica were highly frequent species parasites in his studied population (6), also compatible with study in Nigeria by Odongo in 1994 who found that G. lamblia was the most dominated parasite, followed by E.\_histolytica in

Formatted: Font: Italic

Formatted: No underline

fruits and vegetables samples (12). When the results were compared with other studies found lower rates Kappus etal in 2003 and Auta etal in 2017 found that other types of intestinal parasites such as A. lumbricoides was the most common parasites found, whereas G. lamblia and E.\_histoyica were least (8,13). This variation in contaminations may be attributed to geographical location, type and number of samples examined, mothers methods used for detection, different laboratory techniques used, type of water used for irrigation, post harvesting handling methods of such vegetables and even the type of water used to wash vegetables can play an instrumental role in the epidemiology of transmission of parasitic disease Furthermore the highest prevalence found of G.\_lamblia\_may be as a result of the viability of their eggs\_cysts\_in the soil for months and being the commonest parasites in the tropic. This may be due to the rough surface and leaf folds of this vegetable which may retain dirt that can be easily washed (14).

# **Conclusions:**

The overall prevalence of intestinal parasites and bacteria was more pronounced among mothers and their children's. Food handlers, vegetables and fruits showed lower prevalence of infections. *Gardia Lamblia* and *E histolytica* were the most predominated parasites seen microscopically among participants. There was significant association between mothers and their children concerning intestinal parasites.
